1. Introduction

The continuous increase of throughput in optical communication systems driven is currently facing the strong challenge of Kerr nonlinearity distorting optical signals during fiber transmission. There is today a lack of effective methods to deal with nonlinear distortion, and hence, nonlinearity mitigation and compensation techniques for optical communication systems have been receiving a significant research attention over the past years with a dual focus on digital and all-optical techniques. Digital techniques can provide effective compensation within the analog bandwidth of high-speed electronics, i.e. limiting their effectiveness to intra-channel effects. However, all-optical approaches provide the tools to tackle Kerr effects over broader bandwidths, naturally extending the nonlinear compensation to include inter-channel interaction. Among the all-optical approaches, optical phase conjugation (OPC) has a strong potential, as it can be easily implemented through four-wave mixing (FWM) in nonlinear media. Impressive demonstrations have already been reported using highly nonlinear fibers [1,2], periodically poled lithium niobate [3] and some preliminary results have been shown in a silicon waveguide [4,5]. Nonlinear devices based on silicon are particularly beneficial for future integration. However, in [4,5] the polarization sensitivity of the device limited the demonstrations to single-polarization operation.

In this work, we overcome this limitation with a polarization-diversity scheme using a single silicon waveguide to perform dual-polarization OPC. The silicon waveguide has a lateral p-i-n diode for mitigating free-carrier effects, thus increasing the FWM conversion efficiency [6]. Using such an OPC scheme, improvements in signal-to-noise ratio (SNR) and transmission reach are demonstrated for dispersion-managed transmission of five wavelength division multiplexed (WDM) dual-polarization (DP) 16-quadrature amplitude modulation (QAM) channels.

2. Experimental setup

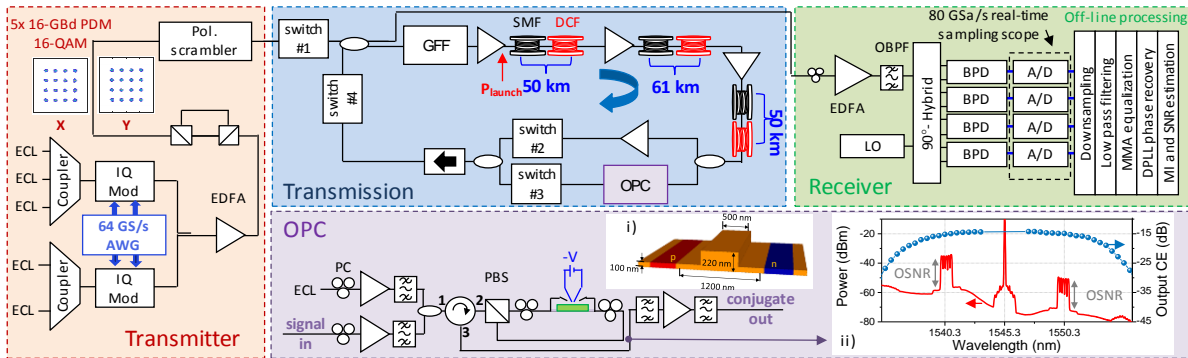

Fig. 1. Experimental setup for the transmission measurements comparing straight transmission to OPC-based transmission. Insets: i) schematic structure of the waveguide with lateral p-i-n diode and ii) optical spectra (red) and CW CE (blue) at port 3 of the circulator in the OPC.

The experimental setup is shown in Fig. 1. Five external cavity lasers (ECLs) on a 25-GHz grid are modulated in two IQ modulators (one for even and one for odd channels) with 16-QAM data at 16 GBd. Polarization multiplexing is emulated and the polarization is scrambled. The channels are launched into a recirculating transmission loop (total loop length of 161 km) consisting of three dispersion-managed spans of standard single mode fiber (SMF) and dispersion compensating fiber (DCF) with lumped erbium-doped fiber amplifiers (EDFAs). Acousto-optical switches enable selecting either the OPC path (switch #3) or simple EDFA-based amplification (switch #2).

The OPC is based on a single-pump (1545.3 nm, 22 dBm pump power) FWM stage in a 3-cm silicon waveguide with a lateral p-i-n diode as in Fig. 1(i). The waveguide, fabricated in the BiCMOS pilot line of IHP [5,6], is characterized by an insertion loss of 11.5 dB at -30 V of reverse bias applied to the diode. The low propagation loss (<1 dB/cm) and lateral diode enable an output conversion efficiency (CE) of -15 dB. The conversion bandwidth is approx. 13 nm (Fig. 1(ii)) and no optical signal to noise ratio (OSNR) degradation is observed after conversion. The grating couplers are strongly polarization sensitive, requiring the use of a polarization-diversity scheme to enable processing of DP signals. The two signal polarizations are split and counter propagated in the same waveguide resulting in two counter-propagating co-polarized FWM processes taking place. At the output of the polarization-diversity loop, the two signal polarizations are recombined with stable relative phase. The DP conjugate idlers are selected by optical bandpass filters (OBPFs) and further transmitted in the recirculating loop before being received in a pre-amplified coherent receiver based on 80-GSa/s analog-to-digital (A/D) converters followed by offline digital signal processing (as listed in Fig. 1).

3. Transmission results

The signal performance after transmission has been evaluated in terms of mutual information (MI) and received SNR estimated from the received waveforms as in [7]. MI and SNR are measured as functions of the launched power into each transmission span and comparison between *straight* (no OPC) and *OPC* (OPC after three loop turns) transmission is shown in Fig. 2. OPC shifts the optimum launched power by approx. 3 dB and enables an increase of 0.4 bit/4D symbol in MI and of 1.2 dB in SNR for 966-km transmission (OPC after 483 km). Additionally, after 1127-km of OPC transmission (7 loop turns, OPC still after 483 km), the signal quality is still higher than for straight transmission after 966 km, resulting in a transmission reach extension of 16 %. Finally, the constellation diagrams of Fig. 2(c) further highlight the signal quality improvement by the nonlinearity compensation achieved by OPC in the silicon waveguide.

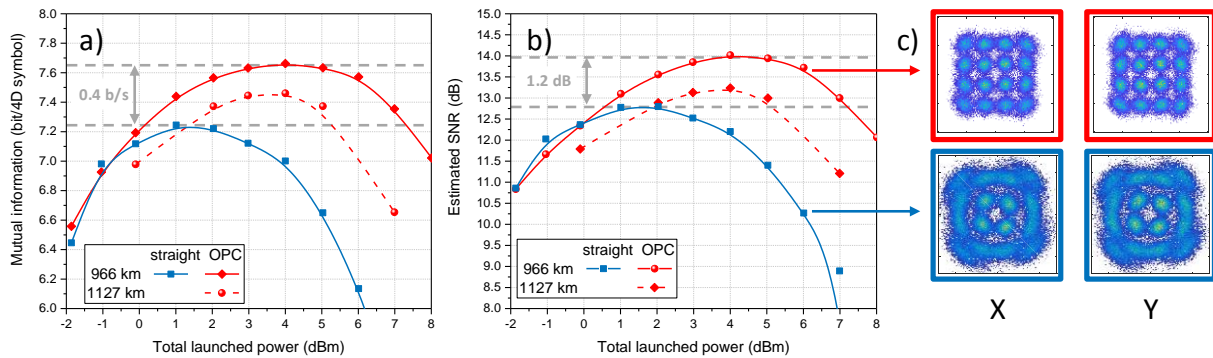

Fig. 2. Estimated receiver MI (a) and SNR (b) of the central WDM channel for straight and OPC-based transmission. c) Constellation diagrams for 966-km straight (blue, bottom) and 966-km OPC-based (red, top) transmission at a launched power of +6 dBm.

4. Conclusions

A dual-polarization OPC scheme using a silicon waveguide with a lateral p-i-n diode enables nonlinearity compensation of PDM data signals in a dispersion-managed transmission link. Signal-to-noise ratio and transmission reach improvements of 1.2 dB (SNR) and 16 % are reported, respectively, by using the OPC scheme.
